## Introduction

Implantable cardioverter defibrillators (ICDs) are electronic devices that can prevent sudden cardiac death (SCD) caused by arrhythmic events in patients.

The latest ESC/EAS and ACC/AHA Guidelines deem the placement of an ICDs appropriate in patients with heart failure class NYHA II and III in the presence of an ejection fraction less than or equal to 35% [1,2]. ICDs are usually not indicated in either class I or IV patients. The Guidelines recommendations for primary prevention of SCD with ICD implantation do not take into account the age of the patients but only their life expectancy which must be at least 1 year.

Our patients usually are over eighty years old with heart failure and severely reduced ejection fraction. We must consequently decide if it is right to implant these patients with an ICD. Is the use of ICD in the patients over 80, in particular over 90 years old, really make sense becomes particularly important considering demographic changes that await us in the coming decades.

## Demographic considerations

In the last decades, there has been a progressive change in the worldwide population, called “demographic transition.” It is characterized by the transition from a traditional demographic regime to a modern demographic regime characterized by low levels of both births and deaths. It is based on high levels of both birth rates and mortality, especially for children [3] (Figure 1).

It is more evident in developing countries and is associated with the progressive aging of the population. In particular, Italy is involved in this change and represents one of the longest-lived populations with better health status [4]. In indeed, in 1863 the median age of death in Italy was 49.29 years, in 1901 it was 62,46 years and in 1951 it was 71.11 years (ISTAT data 2007). Today the life expectancy at birth is 80.8 years for men and 85.2 for women. According to the

annual report of the Institute of Statistics, currently, there are almost fifteen thousand over 100 people in Italy. The aging of the population is certainly due to medical progress as well as researches and to the diffusion of healthy lifestyles and habits (e.g. sport, cultural participation) that influences improvement of health status. Nevertheless, because of these changes, the incidence of chronic diseases is increased. In particular, it is increasing the prevalence of heart failure and ventricular dysfunction and the first causes of death in older people are cardio-circulatory diseases, following by cancers. Moreover, the burden of electrophysiological disease in elderly patients is continuously rising. Atrial fibrillation and sick sinus syndrome are regarded as “geriatric conditions” and ventricular arrhythmias in failing hearts affect a large number of older people [5]. To treat, life threatening arrhythmias, the implantation of permanent pacemakers (PMK), ICDs and cardiac resynchronization therapy (CRT), are increased in the last decades. Decision about if device-based therapy is necessary in older people (over eighty years, in particular over ninety years) remains particularly challenging. Indeed, these therapies may influence the change in less morbidity and mortality in selected patients with heart failure and potential life-threatening arrhythmias (primary prevention). On the other hand, the complex comorbidity of many older patients makes them more exposed to the risk of mortality and peri-procedural complications [6].

### Ventricular arrhythmias and SCD in the elderly

Premature ventricular beats (PVBs) are frequent in the elderly, and that is associated with a worse prognosis even in the absence of underlying cardiomyopathy [7]. The main causes of sustained ventricular arrhythmias in the elderly are ischaemic heart disease and dilated cardiomyopathy. In this setting of patients, frequent is an iatrogenic cause [8]. QT prolongation caused by neurological drugs or secondary to the use of antiarrhythmic drugs can lead to “torsades de pointe” which can result in SCD.

In older patients SCD may be caused mainly by malignant ventricular arrhythmias, monomorphic ventricular tachycardia (VT) or primary ventricular fibrillation (VF). In 17% cases, is secondary to bradycardia [9] and the primary cause is coronary artery disease. The elderly population has an increased incidence of SCD. The annual incidence in an 80-year-old man is about 7 times greater than in a 40-year-old man [20]. In women this trend is much more marked. The incidence of SCD in a woman over 70 is 40 times greater than in a 45-year-old woman [11]. However, in the elderly non-sudden death increases much more than SCD, so the consequent SCD/all-cause mortality ratio is progressively

reduced with advancing age. This phenomenon is called “the paradox of SCD in the elderly” and derived by the fact that the elderly are a population with high baseline all-cause mortality risk in which comorbidities play an important role. In the presence of multiple and severe comorbidities the risk of non-sudden death is higher and this population may not benefit from the use of a device that reduces the risk of SCD.

### Evidence in favor of ICD in the elderly

In ICD trials performed so far, the elderly, have been poorly researched. A relatively high number of elderly patients have been enrolled in the MADIT II trial, where about 20% of patients were over 75 years old [12]. A subgroup analysis of this study, Huang DT, demonstrated that elderly patients (204 patients aged more than 75 years) have the same reduction in mortality compared to younger patients (HR 0.56; 95% C.I, 0.29-1.08 vs HR 0.56; 95% C.I, 0.29-1.08) [13]. However, the follow up in patients  $\geq 75$  years was short (17.2 months) as well as patients  $< 75$  years old (20.8 months). Kong et al., in a meta-analysis including data from four trials on the use of ICD in primary prevention (MUST, MADIT-II, DEFINITE and SCD-HeFT), demonstrated that ICD use is effective in reducing all-cause mortality in patients  $\geq 75$  years of age [14]. Chan, et

al. in a prospective cohort of 965 patients with and without ischaemic cardiomyopathies (EF  $\leq$  35%) significantly older than those in primary prevention trials, compared long-term mortality in patients who did and did not receive ICDs over a mean follow-up of  $34 \pm 16$  months [15]. This study confirmed that the use of ICDs was associated with lower all-cause mortality among older patients and patients with a limited number of major co morbidities. under-represented. Moreover 45-day complications were not increased in elderly patients. Data from a registry of cardiac resynchronization therapy-defibrillator (CRT-D) patients of the University of Pittsburgh, demonstrated, that mortality among CRT-D recipients  $\geq$  80 years old is higher than in younger patients but isn't excessive [17]. Also the risk of inappropriate shocks in older patients is relatively low and significantly less than in younger patients suggesting that CRT-D should be given due consideration in elderly patients with heart failure (HF). Further confirmation that ICD implantation is safe in the elderly was a study of Al-Khatib, et al. that studied 8581 patients aged  $\geq$  65 years who received and ICD [18]. In this study age was not an independent risk factor for increased complications after device implantation.

### Evidence against ICD in the elderly

In the trials of primary prevention of SCD with ICD, MADIT-II and SCD-HeFT, the benefit of the device appears clear only in a mid- to long-term follow-up (2-5 years). Still, the median survival of elderly patients with an ICD in most studies that have been seen, is  $<$  5 years [19]. Therefore, the effectiveness of the ICD in extending life expectation seems marginal. A meta-analysis on pooled data from three trials (DEFINITE, SCD-HeFT and MADIT) do not demonstrate a significant survival benefit for the ICD in the elderly [20]. Fauchier, et al. in a French registry of 5534 primary prevention ICD recipients, demonstrated, that older age was independently associated with a higher rate of early complications and a lower rate of inappropriate therapies [21]. In the secondary prevention setting, a meta-analysis on pooled data from three trials (AVID, CIDS and CASH) documented that ICD implantation did not seem to determine a survival benefit in elderly patients [22]. The DANISH study that evaluated 1116 patients with non-ischemic systolic heart failure, did not demonstrated a benefit on all-cause mortality with ICD implantation. However, the subgroup analysis demonstrated a possible age-dependent correlation between ICD utilization and mortality with survival benefit evident only in the youngest patients ( $\leq$  70 years old) [23].

### Biological and chronological age and the concept of frailty

There are two kinds of ages, chronological and biological. Chronological age is the number of years of one person has been alive. On the other hand, biological age refers to how old a person seems to be. The age, depends on our genetics, but also is impacted by external factors, including diet, exercise, stress, and smoking. Many gerontologists believe that

chronological age does not consider these external factors. In the last decades, we have seen how the improvement of health status in older population increases the opportunity of implantation of PMK, ICDs and CRT. A part of these older patients can present complex comorbidity that makes this population more fragile. Thus, in frailty, there is a difficulty in determining risk-benefit trade-offs when these options are considered for older adults. It has become clear that age alone is insufficient to characterize these patients and determine their eligibility for device-based therapies [24]. The concept of frailty has emerged as a means of better characterizing the resiliency of older adults beyond their age and comorbidities to refine estimates of predicted risk and guide decisions for individualized care. Frailty is a condition, characterized by a loss of biological reserves, which leads to failure of homeostatic mechanisms following stressor events [25]. Frailty, is an emerging concept in modern healthcare due to its association with adverse health outcomes and frequent hospital admissions. The prevalence in hospitalized elderly patients it is estimated to be between 24.7% and 80%. The variability is due to varying populations, definitions and diagnostic criteria [26]. In literature there are many pieces of evidences about the association between frailty and negative outcomes in chronic disease, especially in the cardio-vascular field. Indeed, frailty is correlated to the worst outcomes in patients affected by heart failure and acute coronary syndrome. Frailty is becoming an instrument more frequently used to decision-making in the therapeutic-diagnostic process in elderly patients suffering from specific pathologies. Frailty is certainly an independent predictor of non-response to CRT and a higher risk of hospitalization for HF and mortality [27]. On the other hand, there are few contrasting data regarding the association between frailty and device-based therapy [28]. No frailty index has yet been validated to assess a patient's eligibility for device implantation. Furthermore, there is a different conceptualization of frailty among older people from professional definitions of frailty, across physical, cognitive and social domains T, they reject the application of the concept of frailty to themselves. They also highlight the importance of functional independence to maintain an acceptable quality of life [29]. A recent study shows that there is an agreement between patient-reported and physicians-assigned Clinical Frailty Score in "well" and mildly frail older people. The patient-reported Clinical Frailty Score is lower than that estimated by physicians in "managing-well" people and moderately and severely frail people [30]. Thus, there is discordance in less-frail patients. Finally, there are emerging data that shows that device-based therapies are associated with high levels of patient acceptability and satisfaction [31].

### Importance of comorbidities in patients with indication to ICD

In elderly patients, both cardiac and extracardiac comorbidities are frequent. With regards to cardiac comorbidities, very important is heart failure (HF) that has a prevalence between 10% and 20% in subjects aged 70-80 years

and probably they have the same need for ICD or pacemaker implantation, even if life expectancy is short in these patients [32]. About 50% of HF patients have more than 75 years. In HF patients, 50% present preserved ejection fraction HF. Sudden cardiac death affects 6 to 9 times more frequently in HF patients than in the general population [33].

Diabetes mellitus (DM) is an important independent predictor of morbidity and mortality [34]. However, diabetic patients have the same benefit from ICD therapy as non-diabetic patients, even if they are sicker and they can have a higher mortality rate overall [35]. Moreover, DM is not a predictor of inadequate response to CRT, and diabetic HF patients treated with CRT have similar prognosis as non-diabetic HF patients [36].

The prevalence of atrial fibrillation (AF) increases significantly with age and as the NYHA class increases, it pass from the 5% of NYHA 1 to 40% of NYHA IV in patients with HF [37]. AF is associated with a higher risk of cardiac events and mortality. AF, per se, do not change the indication to use a device in elderly patients, while, it can influence the choice of the device and its mode of operation. Van Boven, et al. showed that in patients treated with CRT-D, AF is an independent risk factor, not only for mortality, but also for appropriate and inappropriate shocks [38].

Chronic kidney disease (CKD) is a severe condition associated with high morbidity and mortality and a decrease in quality of life. SCD is more frequent in patients with CKD and remains one of the primary causes of death among these vulnerable patients [39]. Bansal, et al. in a large cohort of patients who underwent primary prevention ICD implantation, do not found evidence that rates of shocks and ATP therapy were different among those with and without CKD. These results suggest that potential concerns for more frequent or inappropriate ICD therapies should not preclude appropriate primary prevention ICD implantation among patients with CKD who are known to be at high risk for SCD [40].

It follows that older patients with comorbidities and with a reasonable expectation of survival, may have an improvement in their prognosis from the use of devices like ICDs and CRT. The problem is that it is difficult to standardized criteria for define good life expectancy. Some authors have tried to create risk scores to predict mortality in ICD recipients [41].

### Risk scores

Many risk stratification scores have been created to estimate the risk of patients that can receive an ICD involving different parameters.

Goldenberg et al., in a MADIT-II sub-study, developed a simple risk stratification score for primary therapy with ICD [42]. They stratified the patients allocated in the conventional therapy arm according to the presence of five easy clinical

parameters such as age > 70 years, NYHA > II, blood urea nitrogen (BUN) > 26 mg/dl, QRS > 120 msec and atrial fibrillation. The study suggests a U-shaped pattern for ICD efficacy, with evident benefit in intermediate-risk patients and reduced efficiency in lower- and higher-risk subsets. Anné, et al. validated this risk score in a cohort of elderly patients [43]. The authors retrospectively analysed all clinical and survival data of 179 patients  $\geq$  75 years with an ICD. The mortality of the cohort was compared with ICD patients aged 60-70 years originating from the same database and to an age- and a sex-matched cohort of Dutch persons. Survival was worse in elderly patients than younger patients and in the age- and sex-matched group of elderly persons. However, survival was not significantly worse when comparing elderly ICD patients without additional risk factors to the general population.

Another risk score, defined SHOCKED, is based on the analysis of data from more than 45.000 primary prevention ICD patients [44]. The authors studied a development cohort and validation cohort of Medicare beneficiaries receiving ICD and evaluated death prediction within 4 years from ICD implantation. About 40% of these patients were  $\geq$  75 years of age. The model was based on 7 clinically relevant predictors of mortality identified from complete model results:  $\geq$  75 years of age, NYHA III, atrial fibrillation, chronic obstructive pulmonary disease, chronic kidney disease, LVEF  $\leq$  20%, and diabetes mellitus. This model accurately identifies patients at highest risk for death after device implantation.

Another algorithm was developed by Kraaier, et al. that studied 861 prophylactic recipients with ischaemic or non-ischaemic dilated cardiomyopathy (DCM) [43]. Four clinical parameters were considered: age  $\geq$  75 years, LVEF  $\leq$  20%, history of atrial fibrillation and estimated glomerular filtration rate (GFR)  $\leq$  30 mL/min/1.73m<sup>2</sup>. The co-presence of these factors influenced the mortality of the patients, and this data, subsequently, was validated in 706 primary prevention patients [45].

Chong, et al. demonstrated that clinical comorbidities (liver or respiratory or renal dysfunction, anaemia, prior cerebral vascular injury) act synergistically to increase mortality risk. Patients with clinical markers involving  $\geq$  2 organ systems had a 38% 1-year mortality rate despite the ICD implantation [46].

### Conclusion

The researches we have described in this review could assist in our understanding of current recommendations that only elderly patients with a reasonable expectation of survival, with good functional status for one year, should receive ICDs. As there is no standardization of a 'reasonable expectation of survival, physicians generally rely on their clinical judgment. To quantify the impact of a specific organ dysfunction on survival, it is necessary to use a multidisciplinary assessment. Elderly patients that still have a discrete survival probability

could be the target of ICD implantation, in particular when there are no additional clinical risk factors. The presence or absence of additional clinical risk factors should be considered when deciding to implant an ICD since they strongly correlate with survival. The use of a risk score can help physicians when deciding if the patient needs to be addressed to ICD implantation.
